Abstract: Catastrophe Markov chain population models have received a lot of attention in the recent past. Besides systematic random immigration events promoting growth, we study a particular case of populations simultaneously subject to the effect of geometric catastrophes that cause recurrent mass removal. We describe the subtle balance between the two such contradictory effects.

Keywords: Markov chain, random population growth, geometric catastrophic events, recurrence/transience transition, height and length of excursions, extinction events, time to extinction, large deviations

1. Introduction

Besides systematic immigration events, populations are often subject to the effect of catastrophic events that cause recurrent mass removal. This results in a subtle balance between the two contradictory effects. Many Markov chains models have been designed in an attempt to explain the transient and large-time behavior of the size of such populations. Some results concern the evaluation of the risk of extinction and the distribution of the population size in the case of total disasters where all individuals in the population are removed simultaneously\(^1\).\(^2\). Other works deal with the basic immigration process subject to either binomial or geometric catastrophes; that is when the population size is iteratively reduced according either to a binomial or a geometric law\(^3\).\(^4\). Such Markov chains are random walks on the non-negative integers (as a semigroup) which differ from standard random walks on the integers (as a group) in that a one-step move down from some positive integer cannot take the walker to a negative state, resulting in transition probabilities being state-dependent.

The binomial effect is appropriate when, on a catastrophic event, the individuals of the current population each die or survive in an independent and even way, resulting in a drastic depletion of individuals at each step\(^4\).\(^5\).\(^6\).

The geometric effect corresponds to softer deletion cases where the sequential decline in the population keeps going on but is stopped as soon as the current population size is exhausted. In more precise words, if a geometric catastrophic event occurs, given the chain is in state \(x\), the population shrinks by a random (geometrically distributed) amount so long as this amount does not exceed \(x\); if it does the population size is set to 0 (a disaster event). In \(4\), this model was called for this reason the ‘truncated geometric’ catastrophe model. This may be appropriate for some forms of catastrophic epidemics or when the catastrophe has a sequential propagation effect like in predator-prey models: the predator kills preys until it becomes satisfied but so long as resources are available. More examples and motivations can be found in Artalejo et al.\(^7\) and in Cairns and Pollett\(^8\), essentially in continuous-times.

In this work\(^4\), we revisited the latter geometric catastrophe model in discrete-time, as a Markov chain on the non-negative integers.

Using a generating function approach, we first discussed the condition under which this process is recurrent (either positive or null) or transient. The recurrence/transience transition is sharp.

In the positive-recurrent case, we described the shape and features of the invariant probability measure. We emphasized that, in the null-recurrent case, no nontrivial invariant measure exists. Focus is then put on the time spent by the walker in the ground state \(\{0\}\). We then showed how to compute the double (space/time) generating functional of the process. Using this representation, we derived the generating functions of the first return time to zero (the length of the excursions) and of the first extinction time when the process is started at \(x_0 > 0\). In the recurrent case, extinction occurs...
with probability 1. The harmonic (or scale) function of a version of the process forced to be absorbed in state \{0\} is used to give an expression of the law of the height of the excursions (the maximum population size reached between any two consecutive extinctions).

In the transient case, after a finite number of visits to \{0\}, the chain drifts to \(\infty\). We first emphasized that no nontrivial invariant measure exists either. Using the expression of the double generating functional of the process, we gain access to a precise large deviation result. The harmonic (or scale) function of a version of the process forced to be absorbed in state \{0\} is then used to give an expression of the probability of a first extinction. The law of the height of the excursions is also derived, with an atom at \(\infty\).

More complex growth/collapse or decay/surge models in the same vein, although in the continuum, were considered in [9-11], where physical applications were developed, such as queueing processes arising in the physics of dams or stress release issues arising in the physics of earthquakes.

2. Geometric catastrophes

Let us introduce the process under concern, as a Markov chain\[^3-4\].

The model.

Birth (growth): Let \((\beta_n)_{n \geq 1}\) be an independent identically distributed (iid) sequence taking values in \(\mathbb{N} := \{1, 2, \ldots\}\), with 
\[
\beta_x := \mathbb{P}(\beta_1 = x), \quad x \geq 1.
\]
We shall let \(B(z) := \mathbb{E}(z^{\beta})\) be the common probability generating function of the \(\beta\)s.

Death (depletion): Let \((\delta_{n})_{n \geq 1}\) be an iid shifted geometric\((\alpha)\)-distributed sequence \[A geometric(\alpha) rv with success probability \alpha takes values in \(\mathbb{N}\)] with success parameter \(\alpha \in (0,1)\). With \(\tilde{\alpha} := 1 - \alpha\), \(\delta_1\) then takes values in \(\mathbb{N}_0 := (0, 1, 2, \ldots}\) with 
\[
\mathbb{P}(\delta_1 = x) = d_x = \alpha \tilde{\alpha}^x, \quad x \geq 0.
\]

Consider the Markov chain with temporal evolution\[^4\]:

\[
X_{n+1} = X_n + \beta_{n+1} \quad \text{with probability } p
\]

\[
= (X_n - \delta_{n+1}), \quad \text{with probability } q = 1 - p.
\] (1)

At each step \(n\), the walker moves up with probability \(p\) and the amplitude of the upward move is \(\beta_{n+1}\). The number of step-wise removed individuals (whenever available) is \(\delta_{n+1}\), with probability \(q\) : the distribution of the sizes of the catastrophes \(\delta_{n+1}\) does not depend on the current size of the population, so long as there is enough prey. Stated differently, given the population size is \(x\) at \(n\), the magnitude of the downward jump is \(x \wedge \delta_{n+1}\).

Note that if \(X_n = 0\), then \(X_{n+1} = \beta_{n+1}\) with probability \(p\) (reflection at 0) and \(X_{n+1} = 0\) with probability \(q\) (absorption at 0).

The one-step stochastic transition matrix \(P\) (obeying \(P1 = 1\), where \(1\) is a column vector of ones) of the Markov chain \(\{X_n\}\) is:

\[
P(0,0) = q, \quad P(0,y) = pb_y, \quad y \geq 1
\]

\[
P(x, y) = qd_{x-y} = q\alpha \tilde{\alpha}^{x-y}, \quad x \geq 1\% \text{ and } 1 \leq y \leq x
\]

\[
P(x, 0) = q\sum_{k \geq x} d_k = q\alpha^x, \quad x \geq 1 \text{ and } 0 = y < x
\]

\[
P(x, y) = pb_{y-x}, \quad x \geq 1 \text{ and } y > x.
\] (2)

With \(\pi_n := (P_{x}(X_n = 0), P_{x}(X_n = 1), \ldots)\) the column vector [In the sequel, a boldface variable, say \(x\), will represent a column-vector so that its transpose, say \(x^t\), will be a row-vector.] of the states’ occupation probabilities at time \(n\), \(\pi_{n+1} = \pi_n^d P, \quad X_0 \sim \delta_{\tilde{\alpha}^0}\) is the master equation of its temporal evolution. An equivalent recurrence for the probability generating function of \(\{X_n\}\) started at \(X_0 = x_0\) is:
Lemma 1 With $\Phi_n(z) := E_{X_0}(z^{X_n}) = \sum_{x \geq 0} z^x P_{x_0}(X_n = x)$, such that $\Phi_0(z) = z^{x_0}$, it holds,

$$\Phi_{n+1}(z) = \left( pB(z) - \frac{q\alpha z}{\alpha - z} \right) \Phi_n(z) + q \left( 1 + \frac{\alpha z}{\alpha - z} \right) \Phi_n(\alpha). \quad (3)$$

Proof. From (2),

$$\Phi_{n+1}(z) = \pi_{n+1}(0) + pB(z) \Phi_n(z) + q \sum_{j \geq 1} z^j \sum_{x \geq j} \pi_n(x) \alpha^{x-j}$$

$$= \pi_{n+1}(0) + pB(z) \Phi_n(z) + \frac{q\alpha z}{\alpha - z} \left( \Phi_n(\alpha) - \Phi_n(z) \right)$$

$$\Phi_{n+1}(0) = \pi_{n+1}(0) = q\Phi_n(\alpha).$$

Remark: The geometric Markov chain is time-homogeneous, irreducible and aperiodic. As a result, all states are either recurrent or transient.

3. The recurrent case

The geometric Markov chain being either transient or recurrent, we shall first exhibit when this transition occurs. We shall then deal first with the recurrent case before switching to the transient regime.

3.1 Existence and shape of an invariant probability measure

Theorem 2 The chain $\{X_n\}$ with geometric catastrophe is ergodic if and only if $\rho := E(\beta_1) < \rho_c := q^{-1} \frac{\alpha}{\alpha} < \infty$. The probability generating function of is then given by (4).

Proof. If a limiting random variable $X_\infty$ exists, from (3), it has probability generating function $\Phi_{\infty}(z) := E(z^{X_\infty})$ obeying

$$\Phi_{\infty}(z) = \frac{\alpha (1 - z) q \Phi_\infty(\alpha)}{(\alpha - z)(1 - pB(z)) + q\alpha z} = \frac{N(z)}{D(z)}.$$

Suppose $\rho := B'(1) = E(\beta_1) < \infty$. Only in such a case does the numerator $N$ and denominator $D$ both tend to 0 as $z \to 1$ while the ratio $\Phi_{\infty}$ tends to 1, as required for $\Phi_{\infty}(z)$ to be a probability generating function. By L’Hospital rule $\frac{N(z)}{D(z)} \to 1$ as $z \to 1$, leading to

$$\Phi_{\infty}(\alpha) = \frac{q\alpha - p\alpha\rho}{q\alpha}.$$ 

Thus

$$\pi(0) := P(X_\infty = 0) = \Phi_{\infty}(0) = q \Phi_{\infty}(\alpha) = q - p\alpha\rho / \alpha,$$

and, with $\Phi_Y(z) := q'(1 - pB(z))$ the probability generating function of a random variable $Y$ obtained as a shifted-geometric($q$) convolution of the $\beta$s

$$\Phi_{\infty}(z) = \frac{(1 - z)(q\alpha - p\alpha\rho)}{(\alpha - z)(1 - pB(z)) + q\alpha z} = \Phi_Y(z)(1 - z)(q\alpha - p\alpha\rho) \frac{(\alpha - z)q + q\alpha z\Phi_Y(z)}{(\alpha - z)q}$$. 

\[ \pi(x) := \pi_\infty(x) = \left[ z^x \right] \Phi_\infty(z) = \Phi_\infty(0) \left[ z^x \right] \frac{1-z}{(\alpha-z)\left(1-pB(\frac{z}{\alpha})\right) + q\alpha z}, \ x \geq 1. \]

If and only if \( \rho = E(\beta) < \infty \) and \( \zeta := \alpha(1 + q^{-1}pp) < 1 \) (\( \rho < \rho_c \)) and the Markov chain is ergodic (positive recurrent and aperiodic). The probability generating function of the invariant probability measure then takes the alternative form

\[ \Phi_\infty(z) = (1-\zeta)\Phi_Y(z) \left[ 1 - \frac{1-z\Phi_Y(z)}{1-z} \right]^{-1}. \]

Note that, with \( \Phi_Z(z) := \frac{1-z\Phi_Y(z)}{1+m(1-z)} = \frac{1-\Phi_{Y+1}(z)}{\mathbb{E}(Y+1)(1-z)} \), the probability generating function of some random variable \( Z \), this is also

\[ \Phi_\infty(z) = \Phi_Y(z) \frac{1-\zeta}{1-\zeta\Phi_Z(z)}. \] (4)

which is the product of the probability generating function of \( Y \) times the one of a shifted compound geometric\((1-\zeta)\) random variable with compounding probability generating function \( \Phi_\infty(1-z) \) (the delay probability generating function of \( Y+1 \)).

Note

\[ \zeta < 1 \iff pE(\beta_1) = pp < \frac{\alpha}{\alpha} = qE(\delta_1), \]

observing \( \alpha / \alpha = E(\delta_1) \). This is a sub-criticality condition stating that the one-step unlimited average move down \( qE(\delta_1) \) must exceed the average move up \( pp \) of the geometric chain.

**Corollary 3** If \( \rho < \rho_c \), the random variable \( X_\infty \) exists and is infinitely divisible (compound Poisson).

**Proof.** Consider first the random variable \( Y \) with probability generating function \( \Phi_Y(z) := E(z^Y) = \frac{1}{1-pB(z)} \). It is a compound shifted-geometric random variable with compounding random variable \( \beta \). It is infinitely divisible because \( \Phi_Y(z) = \exp(-\lambda(1-\psi(z))) \) for some \( \lambda > 0 \) and some probability generating function \( \psi(z) \) with \( \psi(0) = 0 \). Indeed, with \( q = e^{-\lambda} \), there exists a probability generating function \( \psi \) solving \( \Phi_Y(z) := q/(1-pB(z)) = \exp(-\lambda(1-\psi(z))) \). It is

\[ \psi(z) = -\frac{\log(1-pB(z))}{-\log q}, \]

which is recognized as the probability generating function of a Fisherlog-series random variable. Shifted-geometric convolution random variables are infinitely divisible. For the same reason, the random variable with probability generating function \( \frac{1-z}{1-\zeta\Phi_Z(z)} \) is infinitely divisible as a shifted-compound geometric random variable with compounding random variable \( Z \). From (4), \( \Phi_\infty(z) \) is the product of these two probability generating functions and so is itself the probability generating function of an infinitely divisible random variable \( X_\infty \).

Miscellaneous:

Neuts\(^4\) observed that if \( \beta \) is itself geometrically distributed (more generally of phase-type), then so are \( Y, Z \), together with \( X_\infty \), so with an explicit expression of \( \pi(x) \). The random variable \( X_\infty \) in particular admits geometric tails. Discrete phase-type random variables are the ones obtained as first hitting times of the absorbing state of a terminating Markov chain with finitely many states\(^{12}\).

In the general case for the law of \( \beta \), an expression of \( \pi(x) := [z^x] \Phi_\infty(z) \) can be obtained from (4), in principle, using
the Faa di Bruno formula\textsuperscript{[13]}, observing $\Phi_{\alpha}(z) = H(B(z))$ for some generating function $H$, as a composition of generating functions.

We also have: $\mu := E(X_\infty) < \infty \Leftrightarrow E(Y^2) < \infty \Leftrightarrow E(\beta^2) < \infty$, owing to: $E(Y^2) = 2E(Y^2) + E(G)E(\beta^2)$, $E(G) = p/q$.

Specifically, if $E(\beta^2) < \infty$

$$\mu = m + \alpha \left( \frac{E(Y^2) - E(Y)^2}{2(1 - \zeta)} \right) = m \left( 1 + \frac{\alpha E(\beta) m + E(\beta^2)}{2(1 - \zeta)} \right).$$

More generally, it can also be checked that if $\beta$ only has moments of order $q < 1 + a(a > 0)$, then $X_\infty$ only has moments of order $q < a$.

Finally, with $m = \Phi'(1) = E(Y) = q^{-1}p\rho = q^{-1}pE(\beta)$, as $z \to 1$

$$\frac{1 - z\Phi'(z)}{1 - z} \sim \frac{1 - z\left(1 - m(1 - z)\right)}{1 - z} \sim 1 + m,$$

so that

$$\Phi_{\alpha}(1) \sim (1 - \zeta)\left[1 - \alpha(1 + m)\right]^{-1} = 1.$$

In the positive recurrent case, the geometric process is not time-reversible with respect to the invariant probability measure $\pi$: there is no detailed balance.

Considerable simplifications are expected when $\beta \sim d$: in this case, the transition matrix $P$ in (2) is of Hessenberg type, that is lower triangular with a non-zero upper diagonal. The corresponding process is skip-free to the right.

3.2 Time spent in the ground state $\{0\}$

Whenever the process $\{X_n\}$ is ergodic, it visits infinitely often all the states, in particular the state $\{0\}$, and a sample path of it is made of iid successive non-negative excursions (arches) through that state. By the ergodic theorem, the asymptotic fraction of time spent by $\{X_n\}$ in this state is

$$\frac{1}{N} \sum_{n=1}^N I(X_n = 0) \to \pi(0) = P(X_\infty = 0), \text{ almost surely, as } N \to \infty. \quad (5)$$

Let $\tau_{0,0} := \inf(n \geq 1 : X_n = 0 \mid X_0 = 0)$ be the first return time to state $\{0\}$. By Kac’s theorem\textsuperscript{[14]}, its expected value is $E(\tau_{0,0}) = 1/\pi(0)$ where $\pi(0) = a + q(1-p)p\rho$. 

Suppose $\{X_n\}$ enters state $\{0\}$ from above at some time $n_1$. The first return time to state $\{0\}$, $\tau_{0,0} := \inf(n \geq n_1 : X_n = 0 \mid X_{n_1} = 0)$, is:

- either 1 if $X_{n_1}$ stays there with probability $P(0, 0) = q$ in the next step; this corresponds to a trivial excursion of length 1 and height 0.
- or, with probability $p = 1 - q$, $\{X_n\}$ starts a ‘true’ excursion with positive height and length $\tau_{0,0}^+ \geq 2$. Thus,

$$E(\tau_{0,0}) = \frac{1}{\pi(0)} + p E(\tau_{0,0}^+) \quad \text{and} \quad E(\tau_{0,0}^+) = \frac{1}{p} \left( \frac{1}{\pi(0)} - 1 \right) \geq 2, \quad (6)$$

to $p(0) < 1/(1 + 2p)$. Given $\{X_n\}$ enters state $\{0\}$ from above at some time $n_1$, it stays there with probability $P(0, 0) = q$ in the next step, so $\{X_n\}$ will quit state $\{0\}$ at time $n_1 + G$ where $G$ is a geometric random time with success probability $p = 1 - q$. After $n_1 + G$, the chain moves up before returning to state $\{0\}$ again and the time it takes is $\tau_{0,0}^+$. Considering two consecutive instants where $\{X_n\}$ enters state $\{0\}$ from above (defining an alternating renewal process), the mean fraction of
time $\theta$ spent in state $\{0\}$ is:

$$\theta = \frac{E(G)}{E(G) + E(\tau_{0,0}^+)}.$$ 

From the expression $E(G) = 1/\rho$ and the value of $E(\tau_{0,0}^+)$, consistently with (5), we get:

**Proposition 4** In the positive recurrent case, the mean fraction of time $\theta$ spent in state $\{0\}$ is:

$$\theta = \frac{1}{1 + \rho E(\tau_{0,0}^+)} = \pi(0).$$

(7)

### 3.3 No nontrivial ($\neq 0$) invariant measure in the null-recurrent case

If $\zeta = 1$ (or $\rho = \rho_c$), the critical chain is null-recurrent with

$$\pi(0) = \frac{q\overline{a} - \rho \alpha}{\alpha} = \frac{q}{\alpha} (1 - \zeta) = 0 \Rightarrow \pi(x) = 0 \text{ for all } x \geq 1.$$ 

The chain has no nontrivial ($\neq 0$) invariant positive measure.

It is not Harris-recurrent$^{[15-17]}$.

### 3.4 The generating functional of the geometric model

With $x_0 \geq 1$, defining the double generating function

$$\Phi_{x_0}(u, z) = \sum_{n \geq 0} u^n \Phi_n(z) = \sum_{n \geq 0} u^n E_{x_0}(z^n),$$

from (3), we get

$$\frac{1}{u} \left( \Phi_{x_0}(u, z) - z^{x_0} \right) = \left( pB(z) - \frac{qaz}{\alpha - z} \right) \Phi_{x_0}(u, z) + q \left( 1 + \frac{\alpha z}{\alpha - z} \right) \Phi_{x_0}(u, \alpha z),$$

together with

$$\Phi_{x_0}(u, 0) = qu \Phi_{x_0}(u, \alpha).$$

We obtain

$$\Phi_{x_0}(u, z) = \frac{z^{x_0} (\overline{a} - z) + q\alpha u \Phi_{x_0}(u, \overline{a})(1 - z)}{(\alpha - z) \left[ 1 - puB(z) \right] + qazu} = \frac{z^{x_0} (\overline{a} - z) + \overline{a} (1 - z) \Phi_{x_0}(u, 0)}{(\alpha - z) \left[ 1 - puB(z) \right] + qazu}.$$ 

(8)

So far, $\Phi_{x_0}(u, z)$ is unknown since it requires the knowledge of $\Phi_{x_0}(u, \overline{a})$ or $\Phi_{x_0}(u, 0)$.

Letting $\Phi_{x_0}(u, z) =: N(u, z)/D(u, z)$, the denominator $D(u, z)$ vanishes at

$$u = u(z) = \frac{z - \overline{a}}{qaz + p(z - \overline{a}) B(z)}.$$ 

(9)

Note
\[ u(1) = 1 \text{ and } u'(1) = \frac{1}{\alpha}(q\alpha - \alpha p) = \frac{q}{\alpha}(1 - \zeta). \]  
\[ (10) \]

The generating function \( \Phi_{x_0}(u, z) \) is well-defined when \( u < u(z) \) and possibly when \( u = u(z) \) as in the recurrent case.

In the recurrent case \( (\zeta \leq 1) \), \( u(z) \) is concave and monotone increasing on the interval \([\bar{\alpha}, 1]\), owing to \( u'(1) \geq 0 \). The function \( u(z) \) has a well-defined inverse \( z(u) \) which maps \([0, 1]\) to \([\bar{\alpha}, 1]\); this inverse is monotone increasing and convex on this interval. Because in the recurrent case, \( [u^n]\Phi_{x_0}(u, z) \rightarrow \Phi_{x_0}(z) \) as \( n \rightarrow \infty \), \( \Phi_{x_0}(u, z) \) also converges as \( z \rightarrow z(u) \). So both the numerator \( N \) and the denominator \( D \) of \( \Phi_{x_0}(u, z) \) must tend to 0 as \( z \rightarrow z(u) \), meaning (by L'Hospital rule) that

\[
\lim_{z \rightarrow z(u)} \frac{N(u, z)}{D(u, z)} = \lim_{z \rightarrow z(u)} \frac{N'(u, z)}{D'(u, z)}. 
\]

Near \( z = z(u) \),

\[ N(u, z) = A(z) + B(z)\Phi_{x_0}(u, 0) \]
\[ \sim A(z(u)) + B(z(u))\Phi_{x_0}(0, 0) + (z - z(u)) \left[ A'(z(u)) + B'(z(u))\Phi_{x_0}(0, 0) \right] \]
\[ D(u, z) = C(z) - D(z)u \sim (z - z(u)) \left[ C'(z(u)) - D'(z(u))u \right]. \]

imposing \( A(z(u)) + B(z(u))\Phi_{x_0}(0, 0) = 0 \), thereby fixing

\[ \Phi_{x_0}(0, 0) = \frac{z(u)^{x_0}(z(u) - \bar{\alpha})}{\bar{\alpha}(1 - z(u))} = G_{x_0,0}(0) \geq 0. \]
\[ (11) \]

Note \( G_{x_0,0}(1) = \infty \) and \( G_{x_0,0}(0) = P_{x_0}(X_0 = 0) = 0 \). The function

\[ G_{x_0,0}(u) = \sum_{n \geq 1} u^n P_{x_0}(X_n = 0) = \sum_{n \geq 1} u^n P^n(x_0, 0), \]

is the Green kernel of the chain at the endpoints \((x_0, 0)\). The matrix element \( P^n(x_0, 0) \) is the contact probability at 0 at time \( n \), starting from \( x_0 \).

From (8) and (11), we thus get a closed form expression of \( \Phi_{x_0}(u, z) \) when \( x_0 \geq 1 \), as \( (u \in [0, 1]) \)

**Proposition 5** In the recurrent case \( (\zeta \leq 1) \), with \( z(u) \) the inverse of \( u(z) \) defined in (9),

\[ \Phi_{x_0}(u, z) = \frac{z(u)^{x_0}(z(u) - \bar{\alpha})(1 - z) - z^{x_0}(z - \bar{\alpha})(1 - z(u))}{(1 - z(u))(\bar{\alpha} - z)(1 - z(u)) + q\alpha z(u)}. \]
\[ (12) \]

**Remark:** If \( \zeta = 1 \), \( \Phi_{x_0}(u, 1) = 1/(1 - u) \) and \( \Phi_{x_0}(0, z) = z^{x_0} \), as required.

### 3.5 First return time to 0

When \( x_0 = 0 \), observing now \( G_{x_0,0}(0) = P_{x_0}(X_0 = 0) = 1 \),

\[ G_{0,0}(u) = 1 + \Phi_{0}(u, 0) = 1 + \frac{z(u) - \bar{\alpha}}{\bar{\alpha}(1 - z(u))} = \frac{\alpha z(u)}{\bar{\alpha}(1 - z(u))}, \]

with \( G_{0,0}(1) = \infty \) \( (z(1) = 1) \).

This function is the Green kernel at the endpoints \((0, 0)\).
If \( n \geq 1 \), from the recurrence

\[
P_0(X_n = 0) = P^n(0,0) = \sum_{m=0}^{n} P(\tau_{0,0} = m)P^{n-m}(0,0),
\]

we see, from taking the generating function of both sides and observing the right-hand side is a convolution, that the pgf \( \phi_{0,0}(u) = E(u^{\tau_{0,0}}) \) of the first return time to 0, \( \tau_{0,0} \) and \( G_{0,0}(u) \) are related by the Feller relation\(^{[19-20]}\): \( G_{0,0}(u) = 1 + G_{0,0}(u)\phi_{0,0}(u) \). Hence, with \( \phi_{0,0}(0) = 0 \),

\[
\phi_{0,0}(u) = E(u^{\tau_{0,0}}) = 1 - \frac{1}{G_{0,0}(u)} = \frac{z(u) - \bar{\alpha}}{az(u)}, \quad \phi_{0,0}(1) = 1. \quad (14)
\]

In particular, observing \( z'(1) = 1/u'(1) = \frac{\bar{\alpha}}{q(1-\zeta)} \), we get

\[
E(\tau_{0,0}) = \bar{\alpha} z'(1)/\alpha = \frac{\bar{\sigma}}{q(1-\zeta)} \text{ if } \zeta < 1 \text{ (positive recurrence)},
\]

\[= \infty \text{ if } \zeta = 1 \text{ (null recurrence)}.\]

Note as required from Kac’s theorem: \( E(\tau_{0,0}) = 1/\pi(0) \).

### 3.6 Contact probability at 0 and first time to extinction

Also, with \( x_0 \geq 1 \) (\( \phi_{x_0,0}(0) = 0 \)), using (11) and (13),

\[
E\left(u^{\tau_{x_0,0}}\right) = \phi_{x_0,0}(u) = \frac{G_{x_0,0}(u)}{G_{0,0}(u)} = \frac{1}{a} \frac{z(u)^{x_0} - (z(u) - \bar{\alpha})}{z(u)^{x_0}}, \quad (15)
\]

gives the probability generating function of the first hitting time of 0, starting from \( x_0 \geq 1 \) (the first extinction time of the chain). We also get

\[
E(\tau_{x_0,0}) = \frac{z'(1)}{\alpha}(ax_0 + \bar{\sigma}) = \frac{\alpha x_0 + \bar{\sigma}}{q(1-\zeta)} \text{ if } \zeta < 1 \text{ (positive recurrence)},
\]

\[= \infty \text{ if } \zeta = 1 \text{ (null recurrence)}.\]

If \( z''(1) < \infty (\sigma^2(\beta) < \infty) \), the variance of \( \tau_{x_0,0} \) in the positive-recurrent case is finite and found to be

\[
\sigma^2(\tau_{x_0,0}) = \frac{z''(1) + z'(1)}{\alpha}(ax_0 + \bar{\sigma} - \frac{z'(1)^2}{\alpha^2} (a^2 x_0 + 1 - \alpha^2))
\]

\[= x_0 \left( z''(1) + z'(1) - \frac{z'(1)^2}{\alpha^2} \right) + \frac{\bar{\alpha}}{\alpha} \left[ \alpha \left( z''(1) + z'(1) \right) - (1 + \alpha) z'(1)^2 \right].\]

If \( \sigma^2(\beta) = \infty, \sigma^2(\tau_{x_0,0}) = \infty \).

We observe from (14)

\[
\phi_{0,0}(u) = E\left(u^{\tau_{0,0}}\right) = \frac{z(u) - \bar{\alpha}}{az(u)}, \text{ entailing } z(u) = \frac{\bar{\alpha}}{1 - \alpha \phi_{0,0}(u)}.\]
The function $\phi_{0,0}(u)$ being a probability generating function, $z(u)$ is the probability generating function of some random variable $\tau \geq 0$; namely, the one of a compound shifted geometric($\alpha$) probability generating function with compounding probability generating function $\phi_{0,0}(u)$. And $z(u)^{x_0}$ is the probability generating function of the random variable

$$\tau_{x_0} = \sum_{k=1}^{x_0} \tau_k,$$  \hspace{1cm} (16)

where $\tau_k$ is an iid sequence with $\tau_k \sim \tau$. We have thus proven

**Theorem 6** In the recurrent case, the function $z(u)$ is the probability generating function of some random variable $\tau \geq 0$. With $\tau_{x_0}$ defined in (16), the first time to extinction random variable $\tau_{x_0}$ is decomposable as

$$d \tau_{x_0,0} = \tau_{x_0} + \tau_{0,0},$$ \hspace{1cm} (17)

where $\tau_{x_0} \geq 0$ and $\tau_{0,0} \geq 1$ are independent. With $\phi_{0,0}(u)$ given by (14), the probability generating function of $\tau_{x_0}$ is given in (15) with $z(u) = \alpha / (1 - a \phi_{0,0}(u))$.

The function $u(z)$ is explicitly defined in (9) and $z(u)$ can be obtained from the Lagrange inversion formula as follows: develop $u(z)$ as a power series in $\hat{z} = \alpha / \alpha - z$, where

$$u(\hat{z}) = \frac{\hat{z}}{q\alpha + z(q\alpha + pB(\alpha + \alpha \hat{z}))}$$

maps $[0, 1]$ to $[0, 1]$. It can in principle be obtained by Faa di Bruno formula for the composition of analytic functions, observing $\hat{z}^{-1} u(\hat{z}) = u_1(u_2(\hat{z}))$ where $u_1(z) = 1 / (q\alpha + z)$ and $u_2(\hat{z}) = \hat{z}(q\alpha + pB(\alpha + \alpha \hat{z}))$ both with well-defined series expansion near 0. Then, by using Lagrange inversion formula we can get $\hat{z}(u)$ satisfying $u(\hat{z}(u)) = u$ and then also the output

$$E\left(u^{\tau_{x_0,0}}\right) = \frac{1}{\alpha} z(u)^{x_0-1} (z(u) - \alpha) = \hat{z}(u)(\alpha \hat{z}(u) + \alpha) x_0^{-1}.$$  

The probability generating function $z(u)$ is well-defined in the range $u \in [0, 1]$ in the recurrent case and $u \in [0, 1] \rightarrow z(u) \in [\alpha, 1]$ is its range.

### 3.7 Harmonic (scale) function and the height of an excursion (recurrent case)

Suppose $\{X_n\}$, with transition matrix $P$, is recurrent. Let then $P \rightarrow \bar{P}$ with $\bar{P}(0, y) = \delta_{0,y}$, forcing state 0 to be absorbing, corresponding to the substitution of processes: $X_n \rightarrow Y_n := X_{n \wedge \tau_{x_0}}$ (the process $X_n$ started at $x_0$ and stopped when it first hits 0). The matrix $\bar{P}$ is stochastic but non irreducible, having $\{0\}$ as an absorbing class. For the process $Y_n$ with transition matrix $\bar{P}$, eventually $Y_\infty = 0$ with probability 1. The harmonic (or scale) sequence $\phi$ solves:

$$\bar{P}\phi = \phi,$$ \hspace{1cm} (18)

where $\phi = (\phi(0), \phi(1), \ldots)'$ is the right column eigenvector of $\bar{P}$ associated to the eigenvalue 1. With $h \gg 1$ and $x \in \{1, \ldots, h - 1\}$, let

$$\tau_{x,h} = \inf (n \geq 0 : X_n \geq h \mid X_0 = x) \text{ if such an } n \text{ exists},$$

$$= +\infty \text{ if not.}$$

By induction, with $\phi(0) := 0$ and $\tau^{(h)} x := \tau_{x_0} \wedge \tau_{x,h}$
\[ \forall x \in \{1, ..., h-1\}, \forall n \geq 0: \phi(x) = E\phi\left(Y_{n \land \tau_{x,h}}\right) = E\phi\left(X_{n \land \tau_{x,h}}\right). \]

The harmonic function \( \phi \) on \( \{1, ..., h\} \), makes \( \phi(X_{n \land \tau_{x,h}}) \) a martingale. Therefore, as \( n \to \infty \), \( \forall x \in \{1, ..., h-1\} \):

\[
\phi(x) = E\phi\left(X_{\tau_{x,h}}\right) = \phi(0)P\left(\tau_{x,0} < \tau_{x,h}\right) + E\phi\left(X_{\tau_{x,h}}\right)P\left(\tau_{x,h} < \tau_{x,0}\right).
\]

(19)

As \( h \to \infty \), both \( \tau_{x,h} \) and the overshoot \( X_{\tau_{x,h}} \). Assuming there is a solution \( \phi(x) \geq 0 \) such that \( \phi(0) = 0 \) and \( \phi(x) \to \infty \) as \( x \to \infty \), owing to \( \tau_{x,\infty} \) yields

\[
P\left(\tau_{x,h} < \tau_{x,0}\right) = \frac{\phi(x)}{E\phi\left(X_{\tau_{x,h}}\right)} \to 0 = P\left(\tau_{x,\infty} < \tau_{x,0}\right),
\]

(20)

indeed consistent with the guess: \( Y_n \) does not escape, it goes extinct with probability 1, whatever the initial condition \( x \) is.

Let us now consider the problem of evaluating the law of the height \( H \) of an excursion in the recurrent case. Firstly, \( H = 0 \) with probability \( q \) (corresponding to a trivial excursion). Now, for nontrivial excursions, the event \( H \geq h \geq 1 \) is realized whenever a first birth event occurs with size \( \beta_1 \geq h \) or, if \( 0 < \beta_1 < h \), when the time (starting from \( \beta_1 \)) needed to first hit \( \beta_1 \) yields

\[
P(H \geq h) = pP(\beta_1 \geq h) + p\sum_{x=1}^{h-1} P_{\beta_1}(\beta_1 = x)P\left(\tau_{x,h} < \tau_{x,0}\right),
\]

where \( P(\beta_1 = x) = bx \), \( P(\beta_1 \geq h) = \sum_{y \geq h} b_y \) and \( P(\tau_{x,h} < \tau_{x,0}) \) is given in (20). Note \( P(H \geq 1) = p \) and, as required since \( P(\tau_{x,\infty} < \tau_{x,0}) = 0, H < \infty \) with probability 1.

4. The transient case

In the transient case \( (\zeta > 1 \text { or } \rho > \rho_c) \), the denominator of \( \Phi_{u,0}(u(z), z) \) tends to 0 as \( u \to u(z) \) and \( u(z) \) does not cancel the numerator: \( u(z) \) is a true pole of \( \Phi_{u,0}(u, z) \). When \( z \in [\alpha, 1] \), \( u(z) \) is concave but it has a maximum \( u(z^*) \) strictly larger than 1, attained at some \( z^* \) inside \( (\alpha, 1) \), owing to \( u(\alpha) = 0 \), \( u(1) = 1 \) and \( u'(1) < 0 \). We anticipate that for some constant \( C > 0 \) depending on \( x_0 \),

\[
P_{x_0}(X_n = 0) \sim C \cdot u(z^*)^{-n} \text{ as } n \to \infty,
\]

stating that \( \{X_n\} \) only visits 0 a finite number of times before drifting to \( \infty \).

4.1 No nontrivial \((\neq 0)\) invariant measure in the transient case

Before turning to this question, let us observe the following: suppose \( \zeta > 1 \text { or } \rho > \rho_c \), so that the super-critical geometric chain is transient. For the same reason as for the null-recurrent case, the chain has no nontrivial \((\neq 0)\) invariant positive measure either. It is not Harris-transient \([16]\).

4.2 Large deviations

Consider \( v(z) := 1/u(z) \) where \( u(z) \), as a pole, cancels the denominator of \( \Phi_{u,0}(u, z) \) without cancelling its numerator, so

\[
v(z) = \frac{qaz + p(z - \alpha)B(z)}{z - \alpha}.
\]

Over the domain \( 1 \geq z > \alpha \), \( v(z) \) is convex with
\[ v'(z) = pB'(z) - q\alpha \bar{\alpha}(z - \bar{\alpha})^{-2} \quad \text{and} \quad v''(z) = pB''(z) + 2q\alpha \bar{\alpha}(z - \bar{\alpha})^{-3} > 0. \]

Thus

\[ v(1) = 1 \quad \text{and} \quad v'(1) = \frac{p\alpha \rho - q\alpha}{\alpha} = p\rho - q\bar{\alpha}/\alpha. \]

We have \( v'(1) > 0 \) if and only if the chain is transient. In this transient case,

\[ \Phi_n(z) \xrightarrow{n \to \infty} v(z). \]

Define

\[ F(\lambda) := -\log v\left(e^{-\lambda}\right) = \log u\left(e^{-\lambda}\right). \]

The function \( F(\lambda) \) is concave on its definition domain \( \lambda \in [0, -\log \alpha) \). It is first increasing, attains a maximum and then decreases to \(-\infty\) while crossing zero in between. There exists \( \lambda^* \in (0, -\log \alpha) \) such that

\[ \omega^* = F'(\lambda^*) = 0. \]

With \( \omega = F'(0) = v'(1) > 0 \), we get

\[ \Phi(0) = \frac{1}{n} \log P_{x_0}\left(1; X_n \leq \omega\right) \xrightarrow{n \to \infty} f(\omega). \quad (21) \]

This shows the rate at which \( P_{x_0}(X_n = 0) \) decays exponentially with \( n \). Equivalently, with \( z = e^{-\lambda} \), \( P(X_n = 0) \sim C \cdot u(z)\, z^{-n} \) as guessed and the Green series \( \Phi_{x_0}(1, 0) = G_{x_0,0}(1) = \sum_{n \geq 1} P_{x_0}(X_n = 0) \) now is summable for all \( x_0 \geq 0 \) (translating that \( \{X_n\} \) visits \( 0 \) only a finite number of times). In the transient case,

\[ P\left(x_{0,0} < \infty\right) = \frac{\phi_{0,0}(1)}{G_{0,0}(1)} < 1. \]
4.3 The scale function and the extinction probability

In the transient case, the chain \( \{X_n\} \) started at \( x > 0 \) can drift to \( \infty \) before it first hits 0. There is thus only a probability smaller than 1 that \( \{X_n\} \) gets extinct for the first time.

In the transient case, let \( P \to \bar{P} \) with \( \bar{P}(0,y) = \delta_{0,y} \) forcing state 0 to be absorbing, corresponding to: \( X_n \to Y_n := X_{n \wedge \tau_{x,0}} \). The matrix \( \bar{P} \) is stochastic but non irreducible, having an absorbing class. The harmonic (or scale) sequence \( \phi \) solves:

\[
\bar{P}\phi = \phi,
\]

where \( \phi = (\phi(0), \phi(1), ...) \) is a column vector. With \( h \gg 1 \) and \( x \in \{1, ..., h - 1\} \), let

\[
\tau_{x,h} = \inf(n \geq 0 : X_n \geq h | X_0 = x) \text{ if such an } n \text{ exists},
\]

= \( +\infty \) if not.

By induction, with \( \phi(0) = 1 \) and \( r_x^{(h)} := \tau_{x,0} \wedge \tau_{x,h} \)

\[
\forall x \in \{1, ..., h - 1\}, \forall n \geq 0 : \phi(x) = E\phi\left(Y_{n \wedge \tau_{x,h}}\right) = E\phi\left(X_{n \wedge \tau_{x,h}}\right).
\]

The harmonic function on \( \{1, ..., h\} \), makes \( \phi(X_{n \wedge \tau_{x,h}}) \) a martingale\(^{[22]} \). As \( n \to \infty \), \( \forall x \in \{1, ..., h - 1\} \):

\[
\phi(x) = E\phi\left(X_{\tau_x}\right) = \phi(0)P\left(\tau_{x,0} < \tau_{x,h}\right) + E\phi\left(X_{\tau_{x,h}}\right)P\left(\tau_{x,h} < \tau_{x,0}\right).
\]

(25)

As \( h \to \infty \), both \( \tau_{x,h} \) and the overshoot \( X_{\tau_{x,h}} \to \infty \). Assuming there is a solution \( \phi(x) > 0 \) such that \( \phi(x) \to 0 \) as \( x \to \infty \), yields

\[
P\left(\tau_{x,0} < \tau_{x,\infty}\right) = \phi(x),
\]

(26)

indeed consistent with the guess: \( \phi > 0 \) and vanishing at \( \infty \). This expression also shows that \( \phi(x) \) must be decreasing with \( x \).

Note \( P(\tau_{x,0} < \tau_{x,\infty}) = P(X_\infty = 0) \) where \( \tau_x := \tau_{x,0} \wedge \tau_{x,\infty} \). We obtained:

**Proposition 8** In the transient case, with \( \phi \) defined in (24) obeying \( \phi(0) = 1 \),

\[
\phi(x) = P(\tau_{x,0} < \tau_{x,\infty}),
\]

is the probability of extinction starting from state \( x \).

**Remark:** The function \( \bar{\phi} := 1 - \phi \) clearly also is a (increasing) harmonic function so that so is any convex combination of \( \phi \) and \( \bar{\phi} \)[18]. Clearly, \( \bar{\phi}(x) = P(\tau_{x,\infty} < \tau_{x,0}) = P(X_\infty = \infty) \).

4.4 The height of an excursion (transient case)

The law of the height \( H \) of an excursion is given by

\[
P\left(H \geq h\right) = P_0\left(X_1 \geq h\right) + \sum_{x=1}^{h-1} P_0\left(X_1 = x\right)P\left(X_{\tau_x} \geq h\right)
\]

\[
= P_0\left(X_1 \geq h\right) + \sum_{x=1}^{h-1} P_0\left(X_1 = x\right)P\left(\tau_{x,h} < \tau_{x,0}\right),
\]

\[
V_1 \text{ Issue 5(2020)} | 477
\]

Contemporary Mathematics
where \( P_0(X_1 = x) = P(0, x) = pb_x \), \( P_0(X_1 \geq h) = p\sum_{y \geq h} b_y \) and, from (25),

\[
P(\tau_{x,h} < \tau_{x,0}) = \frac{1 - \phi(x)}{1 - \mathbb{E}\left(X_{\tau_{x,h}}\right)}.
\]

Note, as required, that \( H = 0 \) with probability \( q \) and

\[
H = \infty \text{ with probability } \sum_{x \geq 1} P_0(X_1 = x) \phi(x).
\]

### 4.5 Doob transform: conditioning on non-extinction

In the transient case when the chain can either drift to infinity or go extinct, the harmonic sequence \( \phi \) plays some additional role in a conditioning. With \( D_\phi := \text{diag}(\phi(0), \phi(1), ...) \), the matrix

\[
P_\phi := D_\phi^{-1} PD_\phi
\]

is a stochastic matrix. We have \( P_\phi(m, 0) = \delta_{m, 0} \) so that state 0 is inaccessible from any other state than 0 itself: state 0 is isolated and disconnected and so may be removed from the state space. We have\(^{[22-23]}\):

**Proposition 9** In the transient case, \( P_\phi \) is the one-step transition matrix corresponding to the process \( X_{\tau_{\tau,\tau}} \) conditioned not to be absorbed at 0.

**Remark:** this is a selection of paths procedure allowing to focus only on those paths of the transient chain that do not go extinct.

### 5. Concluding remarks

We revisited the geometric catastrophe model in discrete-time, as a Markovian population dynamics on the non-negative integers. For this process, a collapse move from some state is geometrically distributed so long as it does not exhaust the current value of this state. It is balanced by random growth moves with arbitrary distribution. This process may be viewed as a generalized birth and death chain. Using generating function techniques, conditions under which the birth and death competing events yield a process that is stable (recurrent) have been highlighted. When recurrent, the shape of the invariant probability measure was described. When unstable (transient), the chain either drifts to infinity or go extinct, a feature similar to supercritical branching processes\(^{[24]}\). The height and length of excursions, extinction probability, time to extinction, have been studied both in the recurrent and transient setups. The harmonic (scale) function was shown to play an important role in the analysis.

Other interesting random walks in the same spirit, but with different collapse rules, were introduced in \( [4] \). We plan, as we do here for the truncated geometric case, to lift the veil on some of their intrinsic statistical properties which are expected to be of a completely different nature.
